# Benthic Foraminifera and Ostracoda from Virginia Continental Shelf

#### Introduction

Benthic meiofaunas living on continental shelves comprise a significant proportion of the total biomass and species diversity in shallow marine environments and play important roles in shallow marine ecosystem functioning. Two important meiofaunal groups, benthic foraminifers (protists) and ostracodes (bivalved Crustacea), have been especially important in studies of benthic communities living along the U.S. Atlantic continental shelf. Buzas and Culver (1980) estimated that the number of benthic foraminifers in marine environments exceeds 10 6 per square meter and wet-weight biomass ranges from 0.02 to more than 10 g/m². Numerous other studies have documented the zoogeographic and bathymetric distribution of more than 800 species of benthic foraminifera (e.g., Culver and Buzas 1980; Buzas and Culver 1980) and several hundred species of marine ostracodes (Valentine 1971; Hazel 1970, 1975; Cronin 1983) along the U.S. Atlantic coast.

Most previous studies of Atlantic continental shelf foraminifers and ostracodes, however, were conducted at very large spatial and temporal scales. For example, the large USGS/Woods Hole Continental Margin Program which took thousands of Atlantic shelf and slope sediment samples during the 1960's (Emery 1968) provided extensive ostracode zoogeographic data spanning several marine zoogeographic provinces and climatic zones (e.g. Hazel 1970). Likewise, Culver and Buzas (1980) compiled foraminiferal species' distribution data from hundreds of published sources to produce distribution maps of the 150 most common species for the western North Atlantic Ocean. Prior studies of fossil benthic foraminifers and ostracodes of the Atlantic margin have also focused on long-term changes in microfaunal assemblages resulting from glacial-interglacial climatic cycles

(Hazel 1968; Cronin 1988) and from community evolution over millions of years (Buzas and Culver 1984, 1989).

While these studies of living and fossil foraminifers and ostracodes provide excellent baseline information, they are insufficient to understand the small scale distribution of species within a limited region of the continental shelf, nor to understand short-term variability in meiobenthic populations. Such information is essential in the evaluation of potential impacts of short-term environmental disturbances from sand mining, pollution and nutrient influx or high-frequency climatic variability on continental shelf ecosystems.

Our main goal in the present study is to provide baseline information on the abundance and species diversity of foraminifers and ostracodes living in three potential sand mining areas off Virginia Beach. This study was carried out in collaboration with the Virginia Institute of Marine Science, College of William and Mary, in support of the Minerals Management Service program to understand environmental aspects of potential sand mining off the city of Virginia Beach, Virginia.

### Study Area

The study region is located in the warm temperate marine climatic zone of the western North Atlantic Ocean between about 36.7 to 37.91 °N and 75.85 to 75.92 °W.

(Figure 1). The oceanography of the region is dominated by the cool, southward flowing Virginia Coastal Current and the warmer, northward-flowing Gulf Stream/Florida Current. These currents converge near Cape Hatteras where strong isothermal convergence creates thermal barriers to the poleward and equatorward distribution of thermophilic (warm water) and cryophilic (cool water) species respectively. Off southeastern Virginia, the coldest bottom waters usually occur during February and range from about 5 to 10 °C, with generally cooler temperatures closer to shore. The warmest temperatures occur in August-

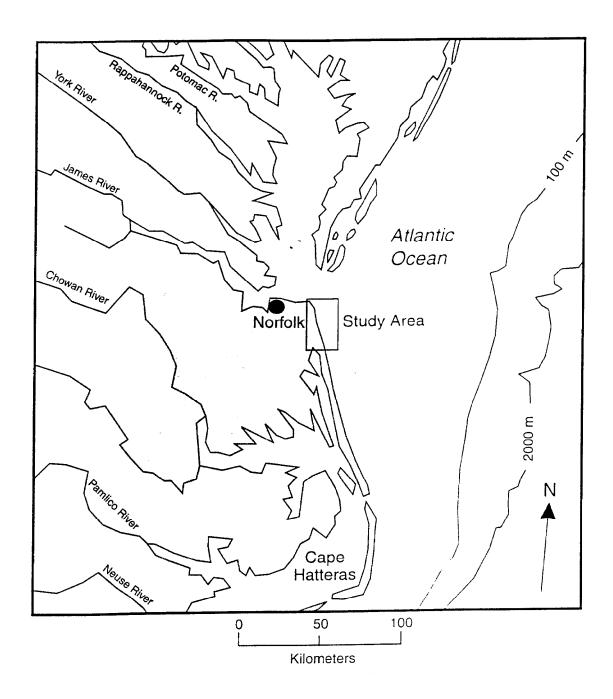

Figure 1: Map showing general location of the Virginia shelf study area.

September when they reach > 25 °C, decreasing offshore to 17-20 °C in the middle shelf region (Walford and Wicklund 1968).

On the geographic scale of faunal provinces, winter and/or summer bottom water temperatures are dominant factors influencing the large-scale latitudinal distribution of ostracode and foraminiferal species on continental shelves (Hazel 1970). The Virginia shelf is located just north of the major zoogeographic boundary near the Cape Hatteras region. The benthic fauna off southeastern Virginia is composed mainly of temperate species common in regions north of Cape Hatteras. Many species living on the Virginia shelf are near the southernmost limit of their latitudinal distribution because either they cannot tolerate warmer water temperatures to the south or they require cooler winter temperatures for survival and/or reproduction (Hazel 1970).

As one moves from nearshore to offshore regions of the Atlantic margin (from the continental shelf to the slope), factors such as dissolved oxygen, light penetration, sediment texture and composition, and decreasing temperatures of the thermocline affect the distribution of species. For example, environmental gradients at the shelf/slope transition result in a major bathymetric turnover of benthic ostracode (Cronin 1983) and foraminiferal species (Culver and Buzas 1983) between 150-500 m water depth. All the samples in the present study came from the mid- to inner continental shelf and the studied fauna is not affected by the thermocline or by hypoxia.

Substrate is another important factor in the small-scale distribution of benthic foraminifers and ostracodes. Buzas *et al.* (1989), for example, conducted experiments with benthic foraminifers and showed a small amount of mud in a sandy benthic habitat can have important affects on benthic foraminiferal densities. Many ostracode species are also substrate-specific in nearshore and estuarine habitats (Cronin 1979). The shelf off southeastern Virginia is mainly composed of sands (Hollister 1973) and provides an ideal substrate for sand-dwelling taxa.

#### Methods

Surface sediment samples were collected on May 15 and June 5-6, 1996 (Spring samples) and October 21 and November 6, 1996 (Fall samples) from the VIMS R/V Bay Eagle. Collections were made from three regions which are referred to here as the northern, central and southern regions. There are no obvious barriers between or environmental differences among the three regions. All three are characterized by sandy substrates and generally similar temperature and salinity regimes. Figures 2-11 show sample stations; Appendices 1-3 give the latitude and longitude for each station.

Additional information about the cruises can be found in the companion report by Cutter and Diaz (1998)

Samples were obtained using a Smith/McIntyre grab sampler. Surface sediment from the uppermost 1-2 cm was scraped from a 10 by 10 cm area within the grab sample and placed in plastic sample bags. The sediment samples were immediately stained shipboard with Rose Bengal to help distinguish between living and dead ostracodes and foraminifera (see Walton 1952).

Surface sediment samples were processed for foraminifera and ostracodes using standard procedures. The sediments were washed through a 63 µm sieve and dried at 50 °C at VIMS laboratories. A total of 300 benthic foraminifers were picked from the residues when available. Samples yielding fewer than 300 specimens were picked of all the foraminifera present. All the samples in Appendices 1 and 2 contained stained representatives and we assume the populations represented at each site were living close to the time of collection. A total of 20 foraminiferal species were found.

Ostracodes were picked at the same time as foraminifers from the same quantity of sediment needed to obtain 300 foraminifers (time constraints did not allow us to pick the entire sample). Ostracodes occurred in most samples; they are typically less abundant than foraminifers in sandy substrates such as those of the Virginia shelf (the number of

ostracodes specimens ranged from 0 to 36 per sample) compared to finer grained substrates of Atlantic estuaries and offshore continental slope regions.

A total of 31 ostracode species were found in the Virginia sandy shelf habitats. Many individual ostracodes (especially *P. edwardst, P. bradyt, C. seminuda*, and *Bensonocythere*) were preserved as whole carapaces containing chitinous appendages and other "softparts". These specimens stained vivid pink and clearly were living at the time of collection. Other specimens, notably juvenile valves, stained faint pink in color and very likely represent the molt stages of living populations.

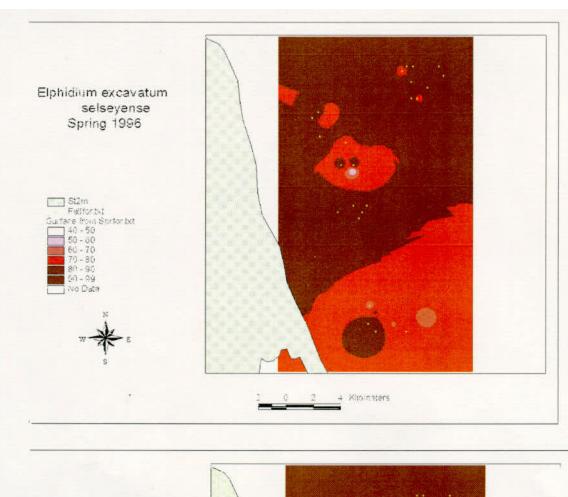

Foraminifera and ostracodes were examined under light and electron microscopes at the U.S. Geological Survey in Reston Virginia. Specimens were identified to species level using USGS reference collections, following the taxonomy of Culver and Buzas (1980) and Loeblich and Tappan (1988) for foraminifers and Valentine (1971), Hazel (1975, 1983), and Cronin (1990) for ostracodes. The faunal slides containing foraminiferal and ostracodes are housed in the USGS microfaunal reference collections, Reston, Virginia 20191.

#### Results

The foraminiferal and ostracode species census data are given in Appendices 1-3 and are available electronically from the authors (teronin@usgs.gov). Figures 2-11 plot the distribution of more common species of foraminifera and ostracodes; Plates 1-5 illustrate most of the identified species with scanning electron photomicrographs.

#### **Ostracodes**

A total of 31 species of ostracode was found in the study area. The ostracode assemblage is dominated by *Peratocytheridea bradyi*, *Hulingsina* spp., *Cushmanidea seminuda*, and *Protocytheretta edwardsi*. These species are typical inhabitants of sandy

inner continental shelf environments of the temperate marine climatic zone of the Atlantic margin off the eastern United States.

The total species number and the composition of the ostracode assemblage is remarkably similar to that collected 30-35 years ago during the USGS-Woods Hole Oceanographic Institution (WHOI) Continental Margin Program (Emery 1966). A comparison between the assemblage found at station 43 of Valentine (1971) located near the current study area with our total 1996 assemblage indicates that Valentine found the same 31 species at this site in the 1960's sample found in the current study. These results leads to a fundamental conclusion from the current study that there has not been a long-term change in the overall ostracode assemblage at this site.

Although the overall ostracode faunal assemblage has not seen any net change over the past 30 years, we discovered important heretofore undiscovered seasonal and onshore-offshore variability in ostracode distributions revealed from the 1996 sampling program (Figures 6-11). Among the highlights:

- Several key ostracode species (*L. williamsi*, *H. rugipustulosa*, *C. seminuda*) have a more limited distribution in the Spring than in the Fall, suggesting there is a seasonal migration into new habitats during the Summer and early Fall months.
- The pattern of Summer/Fall range expansion may be related to the predominant southward direction to bottom drift of this region which may also be related to the prominent sand-swell crests in many regions of the mid-Atlantic shelf (Uchupi 1968; Hollister 1973).
- Several other species contract their range between the Spring and the Fall seasons.
   Peratocytheridea bradyi contracts its range from the northern and southern regions to only the southern region in the Fall. Hulingsina americana and Protocytheretta edwardsi are present in northern/central and northern/southern regions in the Spring,
   respectively, but they are almost totally absent from all samples taken in the Fall.

• The Virginia continental shelf contains several species encountered in sediments deposited over the past 1000 years in Chesapeake Bay. The shelf seems to serve as a source area for ostracodes species which periodically inhabit the more saline southern part and the deeper channel of Chesapeake Bay especially during periods when river discharge is reduced (Cronin unpublished data).

These results provide strong evidence that ostracode species have distinct population ecology linked to seasonal variability of the continental shelf. Major seasonal changes in ostracode populations have also been documented in estuarine ostracodes in the Patuxent River (Tressler and Smith 1948) and in Sippewisset Marsh, Cape Cod (Schweitzer and Lohman 1990) but until this time, were unknown for shelf species. We believe the southeastern Virginia 1996 data is the first to document such seasonality in Atlantic shelf marine ostracode distributions. Although additional analyses are merited to further document seasonal trends, we suspect that seasonal variability is related to bottom water currents. Southward flowing currents are considered especially important in affecting the distribution of *L. williamsi*, *H. rugipustulosa*, *C. seminuda*.

#### Benthic Foraminifera

A total of 20 species were identified from the surficial sediment samples. The dominant genus is *Elphidium*, a genus that includes several species common in nearshore environments of the North Atlantic Ocean. *Elphidium* is represented by three subspecies of *E. excavatum* (these are sometimes referred to separate species or distinct morphotypes of the same species): *Elphidium excavatum clavata*, *E. excavatum selseyensis*, and *E. excavatum excavata*. Figures 2 and 3 show the distributions of *E. excavatum selseyense*, the most abundant species found in our study, and *E. excavatum clavata* during Spring and Fall 1996.

Virginia Beach continental shelf comprising up to 93% of the assemblage. The Spring distribution of *E. selseyensis* shows it comprises greater than 80% of the assemblage in northern and central areas, and 70% to 80% of the assemblage in the southern region. The distribution of *E. selseyensis* in the fall is reduced with a greater than 80% occurrence in the northern and central areas, and 60% to 80% in the southern area and the southern part of the central area.

Elphidium excavatum clavata is the dominant benthic foraminifer in the northern and southern areas. It makes up a much smaller percentage (< 8%) of the assemblage in the central area. This species expands to significant proportions in the fall where it composes greater than 8% (sometimes exceeding 16%) in much of the central and southern regions.

The occurrence off southeastern Virginia of these forms of the genus *Elphidium* is consistent with benthic foraminifer distributions reported from the mid-Atlantic continental shelf of North America. Murray (1991) and Culver and Buzas (1980), for example, mapped the *Elphidium* predominance from Cape Cod to Cape Hatteras and off the North American Atlantic coast, respectively. Schnitker (1971) also abundant *Elphidium clavatum* north of Cape Hatteras on the inner shelf.

Other species occurring on the Virginia shelf, in order of abundance, include Quinqueloculina seminula, Ammonia parkinsoniana, Buccella frigida, Hanzawaia atlanticus, Hanzawaia concentrica and Eggerella advena. Figures 4 and 5 show the distribution of  $\Lambda$ . parkinsoniana and Q. seminulum during Spring and Fall, 1996; plates 4 and 5 illustrate most of these species.

Although the relative abundances of *Ammonia parkinsoniana* in the Virginia Beach shelf samples are low, 5% or less, the distribution of this species seems to reflect distinct environmental conditions in the central study area. *A. parkinsoniana* is common throughout the world in estuarine environments due to its tolerance of highly fluctuating

salinities ranging from brackish (oligohaline, 0.5-5 ppt) to hypersaline (>40 ppt). It lives on the surface of fine-grained sediments down to a depth of 10 cm into the substrate and has a complex life history involving bacterial and algal endosymbionts (Goldstein and Moodley 1993). Chandler *et al.* (1996) found that *Ammonta* would only reproduce in culture under specific conditions that included the addition of silty-clay obtained from the Gulf of Mexico and a regular diet of phytoplankton.

The Spring distribution of A. parkinsoniana shows its greatest abundance in the southern part of the central area with only sparse occurrences in northern and southern regions. The fall distribution of A. parkinsoniana shows a slight expansion into the northern and western sections of the central area 2 but it is still rare to absent in northern and southern regions. It is unlikely that salinity variations restricted A. parkinsoniana from inhabiting northern and southern regions. Rather, we suspect that its limited range has more to do with resource limitations such as the availability of food, nutrients and/or finer grained sediments which may be available in the central region.

Quinqueloculina seminula is the dominant miliolid foraminifer that occurs in our surficial samples. It is present in percentages ranging from 5 10% to 20 25% in the central and southern regions in the Spring. However, its distribution changes in Fall when it expands into the northern region but disappears in parts of the central region. In the Fall its abundance is greatly reduced to < 2 %.

#### Conclusions

The modern benthic foraminiferal and ostracode faunas from three areas on the Virginia Beach continental shelf allow several important new conclusions about the meiobenthic fauna of sandy substrate environments of the continental shelf off Virginia Beach, Virginia.

- The 1996 faunal assemblages are extremely similar in species composition to those obtained in previous sampling program of the North American Atlantic continental shelf conducted during the 1960's. There has been no major long-term changes in the faunas from these regions.
- Seasonal benthic foraminiferal and ostracode distribution data show that significant changes in the relative abundance of the dominant species characterize the Spring and Fall assemblages. Several ostracode species expand their range southward from Spring to Fall suggesting bottom drift currents may play a role in seasonal dispersal of populations. Other ostracode species are common in the Spring but are almost totally absent in the Fall reflecting a complex, still poorly known population ecology.
- Foraminiferal species richness and geographic distributions are slightly greater in the fall with the expansion of the species *E. clavata*, *A. parkinsoniana*, and *Q. seminula*, and reduction in spatial distribution of *E. selseyensis*.
- Ammonia parkinsoniana has a distinct range limited to the central study region,
   possibly due to food and/or substrate limitations.
- The Virginia shelf is an important source habitat for species migrating into Chesapeake
  Bay. Two examples are the ostracode species, *Loxoconcha williamsi* and

  Protocytheretta edwardsi, which occur commonly on the Virginia shelf and have also
  been discovered in sediments in Chesapeake deposited prior to large-scale land clearing
  of the early 19<sup>th</sup> century.

Overall, our preliminary results indicate that a complex meiobenthic community inhabits the southeastern Virginia shelf. It is very likely that the entire community is potentially sensitive to environmental disruption to surficial sediments. However, due to the variable ecological requirements of each foraminiferal and ostracode species, the impact of habitat disturbance will vary widely among the 50 or so species recovered.

Furthermore, whereas the Virginia shelf is itself important habitat for meiobenthic species, this region must also be considered an important source area region for species able to migrate into coastal estuaries and bays like Chesapeake Bay. Consequently, species' population dynamics in the shelf region must be examined in the context of seasonal monitoring of conspecific populations living in adjacent areas.

Additional benthic sampling of the Virginia shelf through a second seasonal cycle, new sampling of the Virginia shelf/Chesapeake Bay mouth transition, supplemented by physical and chemical oceanographic data, would provide an ideal platform from which to fully understand shallow marine foraminiferal and ostracode species ecology and determine the least disruptive way to mine sand from shelf regions.

#### Acknowledgments

This study was conducted by the U.S. Geological Survey and Virginia Institute of Marine Science for Minerals Management Service, Cooperative Agreement No. 14-35-001-30807. We appreciate the encouragement of Barry Drucker of MMS during the course of this program, especially his support of multidisciplinary environmental studies of the continental shelf ecosystems. This study would not have been possible without the support and insights of C. H. (Woody) Hobbs, III and Robert Diaz of VIMS. We are grateful to the captain and crew of the *Bay Eagle* for their assistance in obtaining the samples for this study. Special thanks go to Colleen Cunningham for her diligence and patience in processing and picking foraminifera and ostracodes. Debra Willard kindly provided a useful review of this report.

#### The Department of the Interior

As the Nations's principal conservation agency, the Department of the Interior has responsibility for most of our nationally owned public lands and natural resources. This includes fostering sound use of our land and water resources, protecting our fish, wildlife, and biological diversity, preserving the environmental and cultural values of our national parks and historic places; and providing for the enjoyment of life through outdoor recreation. The Department assesses our energy and mineral resources and works to ensure that their development is in the best interests of all our people by encouraging stewardship and citizen participation in their care. The Department also has a major responsibility for American Indian reservation communities and for people who live in island territories under U.S. Administration.

#### The Minerals Management Service Mission

As a bureau of the Department of the Interior, the Minerals Management Service's (MMS) primary responsibilities are to manage the mineral resources located on the Nations's Outer Continental Shelf (OCS), collect revenue from the Federal OCS and onshore federal and Indian lands, and distribute those revenues.

Moreover, in working to meet its responsibilities, the Offshore Minerals Management Program administers the OCS competitive leasing program and oversees the safe and environmentally sound exploration and production of our Nation's offshore natural gas, oil and other mineral resources. The MMS Royalty Management Program meets its responsibilities by entrusting the efficient, timely and accurate collection and distribution of revenue from mineral leasing and production due to Indian tribes and allottees, States and the U. S. Treasury

the MMS strives to fulfill its responsibilities through the general guiding principles of: (1) being responsive to the public's concerns and interests by maintaining a dialog with all potentially affected parties and (2) carrying out its programs with an emphasis on working to enhance the quality of life for all Americans by lending MMS assistance and expertise to economic development and environmental protection.
